Abstract

In frequent technological processes of food industry or animal science, the use of classification, gradation, calibration or sifting operation becomes a necessity. Sifting is a mechanical operation realized through separation in granulometric factions of some polidisperse mixtures of granules and powder on the basis of particle shape and size. Sifting can be achieved as a stand-alone operation or as a preliminary operation for the preparation of raw materials for further processing operations. Sift method consists in locating the plates one in extension of another, the later having the dimensions of the orifices of the sieves arranged in ascending order. This method presents the advantage of using a small space from the sieving machine, a slight supervision and a good accessibility to perform proper maintenance operations. The vibration motion used in the separation operation can be an advantage only for some raw materials, while for the others it can be a disadvantage because of the congestion particle phenomenon on the plate surface.

INTRODUCTION

Much of the raw materials used in different branches of food industries (cereal crops, vegetables, fruits) and intermediate products or finished goods are solid-solid mix heterogeneous polidisperse systems [1, 3]. In many technological processes it becomes necessary to introduce classification, gradation, calibration or sieving operations.

Classification is the separation process of solid-solid mix heterogeneous polidisperse systems that belong to the same categories of material in granulometric factions or classes after certain criteria. Factions (class material) used in gradation operations are differentiated in terms of granulometric point of view. In terms of physical principle applied, classification can be realized mechanical, pneumatic or hydraulic [1, 3].

Gradation is the operation of heterogeneous particle separation from mixed solid-solid components based on their belonging to a certain category of material (sorting by components).
Separation after the nature of the components can be done on the basis of differences between the physical or chemical constants values (density, color, magnetic susceptibility, solubility etc).

In terms of principle applied, gradation can be realized on the basis of shape differences of the particles (also called sorting), based on different magnetic susceptibility (also called magnetic separation) and based on color (called color sorting).

Calibration is the process of separation by size of various raw materials. It applies both to sort vegetables and fruits and seeds for various agricultural crops.

Sieving (sifting) is a mechanical operation realized through separation in granulometric factions of some polidisperse mixtures of granules and powder on the basis of particle shape and size. Separation is achieved through area separation in shape of metallic fabrics.

Within the technological processes of food industry, sifting can be achieved as a stand-alone operation or as a preliminary operation for the preparation of raw materials for further processing operations [2].

Depending on the purpose, the devices for the sifting operation are called: grates, sieves or plates. During sieving operation, the polidisperse granular mixture is divided into two granulometric categories: sieve residue or superior current and sift or inferior current [3, 4].

Sieving operation can be achieved by two methods: sift method and residue method.

Sift method consists in locating the plates one in extension of another, the later having the dimensions of the orifices of the sieves arranged in ascending order. In this way, every sieve plate receives the residue of previous plate and finally are achieved many sifts and one residue. This method presents the advantage of using a small space from the sieving machine, a slight supervision and a good accessibility to perform proper maintenance operations [3, 4].

The residue method consists in the overlapped location of the plates, one above the other, sieves being arranged in descending order of the sizes of the orifices of the sieves. In this way finally are obtained more residues and one sift. The advantage of this method consists in eliminating the top of the particles protecting large areas of separation of a rapid wear. Sift from the collector is the finest fractions obtained with this method [3, 4].

**MATERIAL AND METHODS**

In order to study the sieving operation four mix polidisperse granular materials were examined: corn, soya-bean groat (SH), sunflower groat (SH) and a mixture of them combined (used for feeding hens and having the following composition: corn
55.39 %, soya SH 20 %, sunflower SH 10 %, oil 1.5 %, starch 2.0%, monocalcium phosphate 1.2%, premix 2004 1.0%, metionyme 0.07%, salt 0.34%, calcium 8.5%). Each of these mixing components were milled in a 25 kW power milling machine from Tehnofavorit Bontida, in 30 min/ton of material (figure 1) samples of material, that are presented in figure 2 being drawn out.

For sifting the material samples was used a sieving machine AS 300 (figure 3) which was passed by an amount of 1.0 kg of each sample material, 10 transitions for each sample in 60 seconds.

On the top of the machine were placed 3 plates and the collector, the plates having mash size of 2.5, 1.25 and 0.63 mm. Machine working mode was set for each sample in part to be firstly continuously and secondly intermittently with an amplitude of vibration of 2.0 mm/g. The intermittent working mode means that the machine through programming would stop every 10 seconds for 2 seconds, afterwards the process being started again. In fig. 4 is shown an aspect of carrying out the sunflower SH sieving operation and in figure 5 an aspect of soy SH.

In figure 6 is shown the balance used to make calculations for mass residues for each sieve used and for the collector.
RESULTS AND DISCUSSIONS

After conducting the sifting operation (10 determinations for each component) were obtained average values of sifts and residues shown in table 1.

Following the sifting operation, the separation efficiency can be determined. The mass flow of the material debit $m_A$ that supplies the plates is divided through the sieving process in two elements: the sift mass flow $m_c$ and residue mass flow $m_R$.

Balance equations regarding mass material flows that are entering and leaving the system and partial balance equations regarding the concentration of the particles that have smaller sizes than the meshes of the sieve are:

$$m_A = m_c + m_{R_1} + m_{R_2} + m_{R_3}$$  \hspace{1cm} (1)

where $m_{R_1}$, $m_{R_2}$ și $m_{R_3}$ are residues on the 3 plates.

$$m_A \cdot \xi_A = m_c \cdot \xi_c + m_{R_1} \cdot \xi_{R_1} + m_{R_2} \cdot \xi_{R_2} + m_{R_3} \cdot \xi_{R_3}$$  \hspace{1cm} (2)

where $\xi_A$, $\xi_c$ and $\xi_{R_{1,3}}$ each represents the percentage of raw materials with smaller sizes than the meshes of the sieve from the initial mixture, sift and residue.
Sieving efficiency in sifting is defined as the ratio between the mass particles with sizes smaller than the size of the meshes of the sieve and that can be located in sifts and material mass flow:

$$\eta_C = \frac{m_C \cdot \varepsilon_C}{m_A \cdot \varepsilon_A} \times [%]$$  \hspace{1cm} (3)

where: \( m_C \) - sift mass flow, \( m_A \) - material mass flow, \( \varepsilon_A \), \( \varepsilon_C \) the percentage of raw materials with smaller sizes than the meshes of the sieve from the sift and initial mixture.

Sieving efficiency in residue is defined as the ratio between the mass particles with sizes bigger than the size of the meshes of the sieve and that can be located in residue and material mass flow [3]:

$$\eta_R = \frac{m_R \cdot (100 - \varepsilon_R)}{m_A \cdot (100 - \varepsilon_A)} \times [%]$$  \hspace{1cm} (4)

where: \( m_R \) - residue mass debit, \( m_A \) - material mass debit, \( \varepsilon_R \), \( \varepsilon_A \) the percentage of raw materials with smaller sizes than the meshes of the sieve from the residue and initial mixture.

Plate’s total efficiency is the result between the separation efficiencies for sifting and for residue[3]:

$$\eta_T = \eta_C \cdot \eta_R \times [%]$$  \hspace{1cm} (5)

The determination of the percentage content of the particles \( \varepsilon_A \), \( \varepsilon_C \) and \( \varepsilon_R \) in residue or sift was done from each sample. Value of these sizes and parameters are shown in table 2.

CONCLUSIONS

1. Due to the very similar quantities of the residues on the sieves and in the collector, the material nature has a low impact on the sieving operation even if vibrations in continuous mode or discontinuous mode were used; if on the first 2 plates the residue quantities are similar in both working modes, in the
collector and on the third plate a greater quantity will be noticed in the
continuous mode as compared to the intermittent mode.

2. Tabular or needle shape of particles makes difficult the sifting process
because even if their thickness allow their passage through the meshes of
the sieve, they deposit in the top of raw materials being prevented from
reaching in contact with the separation area. Also tabular shape particles that
reach the surface of the plate can close the holes which has the effect of
decreasing the capacity of separation.

3. Material granulometric factions affect plate efficiency and the capacity of
the sieve in the process of separation. Hereby, particles with size less than
0.75 of mesh size pass easily through the meshes of the sieve; those particles
with size larger than 1.35 of mesh size remain in residue. Particles that have
size between 0.75…1.35 of the meshes of the sieve generate difficulties in
the sifting process. If it is working with mixtures containing a high
percentage of particles between these critical limits, it is advisable to work
with sieves which have larger mesh size to 10 .. 15% higher.

4. Orifice shape can be adopted according to the geometric shape of the
particles: for sphere particles, are recommended to be used plates with
square or circular orifice shape; for irregular shapes can be used plates with
oblong shape (rectangular).

5. The sizes of the orifices of plates influence the efficiency of the sifting
operation, the efficiency decreasing as the size of the orifice is diminishing.

6. The vibration motion of the plates doesn’t have a notable influence on the
sifting efficiency; the vibration motion used in the separation operation can
be an advantage only for some raw materials, while for the others it can be a
disadvantage because of the congestion particle phenomenon on the plate
surface.
